Abstract

We compute the quark–antiquark potential in three dimensional massive Quantum Electrodynamics for arbitrary fermion mass. The result indicates that screening prevails for any quark masses, contrary to the classical expectations, generalizing our previous result obtained for large masses. We also test the validity of several approximation schemes using a detailed numerical analysis. The classical result is still reproduced for small separation of the quarks.

1 Introduction

A proper study of the problem of screening and confinement is of considerable importance in our understanding of gauge theories. To avoid the complexities of four dimensions these studies are usually confined to lower dimensions. In this framework, a deep physical interpretation has been achieved. Indeed, in two-dimensional QED[1], one obtains screening in the massless case, but confinement in the massive quark case, realizing the expected picture.

For QCD in two dimensions Gross et al [2] were the first to discuss the subject. If dynamical fermions and test charges are in different representations, they find screening or confinement in some particular cases depending on whether the fermion is massless or massive. A similar conclusion in an identical setting has been arrived at for the massless case in [3]. If, on the other hand, all fermions are in the fundamental representation, then screening prevails independently of the quark mass [4].

General inquiries in two dimensional gauge theories have been performed recently by several authors [5], concerning the θ vacuum structure, screening, confinement and chiral condensates. In three dimensions related questions were studied in [6].

In three dimensional space-time, for an abelian gauge group, the question of screening versus confinement has been recently analysed for large fermion masses[7] in which case the fermionic determinant can be computed as a series in the inverse mass. The conclusion was that, contrary to classical expectations, the theory is in the screening phase. Although this is expected from the fact that a Chern-Simons term develops and there is a topological mass generation, it is a further indication that the dynamics of gauge fields and the deep problem of screening versus confinement is far from being settled by a simple inspection of the classical behaviour of the theory. In the case of three dimensional QED, the outcome reveals that the vacuum polarization is once more capable of developing configurations that screen the external quarks, presumably modifying the dynamics of quark-antiquark bound-states.

Here we extend the analysis of our previous work [7] in order to include all values of the fermion mass parameter. An explicit expression for the quark-antiquark potential is obtained following the usual ideas of bosonisation[1, 8] but an analytic form cannot be obtained, and we resort to the use of numerical analysis. The results show that the screening phase obtained in the large mass limit[7] persists for any value of the mass parameter (including vanishing mass). Next, the validity of certain approximation schemes[9] is tested. Using these approximations a simple form of the quark-antiquark potential can be given, which is compared with the exact form. We still obtain screening; moreover the behaviour of the functions is very accurately described by the proposed approximations.

The paper is divided as follows. In section two we present the computa-

tion of the potential and the numerical results. We draw the potential for different values of the mass parameter, showing that its form is essentially the same in the whole range of real values for the mass term, leading to the screening phase. Furthermore, we test the approximation forms of all the functions necessary for computing the potential. Section three is reserved for conclusions and discussions.

2 Computation of the quark-antiquark potential

The partition function of three dimensional massive QED in the covariant gauge, in the presence of an external source J^μ , is given by

$$Z = \int d[\psi, \bar{\psi}, A_\mu] \delta(\partial_\mu A^\mu) \exp \left\{ i \int d^3x [\bar{\psi}(i\rlap{\not{D}} - m - e\rlap{\not{A}})\psi - \frac{1}{4}F_{\mu\nu}^2 + A_\mu J^\mu] \right\} \quad (1)$$

where $F_{\mu\nu}$ is the field tensor, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$.

The bosonised version of the above defined action in the weak coupling approximation is given by the expression[10, 11]

$$Z = \int dA_\mu \delta(\partial_\mu A^\mu) \exp \left\{ i \int d^3x \times \left[\frac{1}{2}A_\mu \Pi^{\mu\nu} A_\nu - \frac{1}{4}F_{\mu\nu}^2 + A_\mu J^\mu + \dots \right] \right\} , \quad (2)$$

where the dots stand for non quadratic terms in the gauge field A_μ . This result will describe the partition function of the Maxwell-Chern-Simons[12] theory in the covariant gauge in the infinite mass limit[7], as we see from the explicit expression for the self-energy of the gauge field, $\Pi_{\mu\nu}$, given by the expression

$$\Pi_{\mu\nu} = H(p) i\epsilon_{\mu\nu\rho} \frac{p^\rho}{p^2} + [G(p) + p^2] \left(g_{\mu\nu} - \frac{p_\mu p_\nu}{p^2} \right) , \quad (3)$$

where the functions G and H are given by the forms

$$H(p) = -\frac{e^2 p^2}{4\pi} \int_0^1 dt \frac{m}{[m^2 - t(1-t)p^2]^{1/2}} , \quad (4)$$

$$G(p) = -p^2 - \frac{e^2 p^2}{2\pi} \int_0^1 dt \frac{t(1-t)}{[m^2 - t(1-t)p^2]^{1/2}} , \quad (5)$$

and $p = \sqrt{-p^2}$. We compute the potential as being the difference between the Hamiltonian with and without a pair of static external charges

separated by a distance L ,

$$\begin{aligned}
V(L) &= H_q - H_0 = -(L_q - L_0) \\
&= -q \int d^2x A_\mu \delta^{\mu 0} [\delta(x^1 + L/2) \delta(x^2) - \delta(x^1 - L/2) \delta(x^2)] \\
&= -q [A_0(x^1 = -L/2, x^2 = 0) - A_0(x^1 = L/2, x^2 = 0)] , \quad (6)
\end{aligned}$$

where we have integrated over the two space components in order to find the potential, and considered the source as corresponding to two fixed charges of magnitude q located at the points defined by the respective delta functions. Note that $L_q(L_0)$ denote the Lagrangeans in the presence (absence) of the charges.

We now consider the equations of motion associated with the action defined by means of (2). The field equation in the covariant gauge reads

$$-H(\partial = \sqrt{-\partial^2}) \epsilon_{\mu\nu\rho} \frac{\partial^\nu}{\partial^2} A^\rho + G(\partial) \left(g_{\mu\nu} - \frac{\partial_\mu \partial_\nu}{\partial^2} \right) A^\nu + J_\mu = 0 \quad (7)$$

Defining the curl of A_μ as

$$\mathcal{A}_\mu = -\epsilon_{\mu\nu\beta} \partial^\nu A^\beta \quad (8)$$

the equation of motion can be expressed as

$$[\square_{nonloc} + m_{nonloc}^2] \mathcal{A}_\mu = -\epsilon_{\mu\nu\beta} \partial^\beta J^\nu - f_{nonloc} J_\mu \quad (9)$$

where

$$\begin{aligned}
\square_{nonloc} &= G(\partial) \\
m_{nonloc}^2 &= \frac{H^2(\partial)}{\partial^2 G(\partial)} \\
f_{nonloc} &= \frac{H(\partial)}{G(\partial)}
\end{aligned} \quad (10)$$

In the absence of sources, and in the large m limit[7], it reproduces the familiar massive mode of Maxwell-Chern-Simons theory[12]. From (6) it is seen that an expression for A_0 is required to calculate the potential. This is given in terms of the curl (8) by

$$\mathcal{A}_2 = -\partial_1 A_0 \quad (11)$$

The time independent solution for $\mathcal{A}_2$ corresponding to the sources describing static quarks can be obtained from (9). Using this result with (11) finally yields, after integrating over the angular variables,

$$A_0(t, L) = A_0(0, L) = -\frac{q^2}{\pi} \int_0^\infty \frac{k J_0(kL)}{\tilde{G}(k) + \frac{\tilde{H}^2(k)}{k^2 \tilde{G}(k)}} dk \quad (12)$$

The integration over the angular variables in the Fourier transformation led to the Bessel function $J_0(kL)$; in the case where the denominator is given by the familiar result (i.e. Feynman propagator, which also appears in the large mass limit, see [7]) the result of the integration is just the modified Bessel function [13].

The potential is now found from (6), (9) and (12), reading

$$V(L) = -\frac{q^2}{\pi} \int_0^\infty \frac{k J_0(kL)}{\tilde{G}(k) + \frac{\tilde{H}^2(k)}{k^2 \tilde{G}(k)}} dk \quad (13)$$

where the functions $G(k)$ and $H(k)$ are given by the expressions

$$G(k) = k^2 + \frac{e^2 m}{4\pi} \left[1 - \left(\frac{2m}{k} - \frac{k}{2m} \right) \arctan \left(\frac{k}{2m} \right) \right] \quad ; \quad (14)$$

$$H(k) = \frac{e^2 m k}{2\pi} \arctan \left(\frac{k}{2m} \right) \quad (15)$$

The above equation takes a particularly simple form in the infinite mass limit,

$$V(L) = -\frac{1}{\pi} \frac{q^2}{1 + \frac{e^2}{6\pi m}} K_0 \left(\frac{e^2}{4\pi} L \right) \equiv -\frac{q_{ren}^2}{\pi} K_0 \left(\frac{e^2}{4\pi} L \right) \quad (16)$$

This reproduces our earlier results in [7]. The asymptotic form of the Bessel function signalizes screening.

For arbitrary mass however, a simple closed form expression cannot be obtained. We therefore have to use numerical methods. They are presented as follows. We first plot the function $V(L)$ given in (13) as a function of L for various values of the mass parameter m . The result is plotted in figure 1. It is immediately obvious that the screening effect is qualitatively independent of the mass, and the quantitative dependence extremely small. Indeed, the graphs are almost bound inside a rather narrow band defined by the results obtained for $m = 0$ and $m = \infty$.

In general, due to the appearance of non algebraic functions the expressions appearing in (14) and (15) are rather clumsy. In reference [9] simple expressions have been derived which, according to the authors, give a good approximation to these functions in the whole range of values of the parameter. The approximations are

$$G(k) \approx k^2 \left\{ 1 + \frac{1}{16} \left[k^2 + \left(\frac{3\pi m}{4} \right)^2 \right]^{-\frac{1}{2}} \right\} \quad , \quad (17)$$

$$H(k) \approx \frac{e^2 m k^2}{4} \left(k^2 + \pi^2 m^2 \right)^{-\frac{1}{2}} \quad . \quad (18)$$

We tested this assumption for the computation of the potential, comparing the asymptotic result with the one obtained with the approximations for $m = 1000$. We repeated the procedure for $m = 0.1$, which shows

Figure 1: *Potential as a function of the distance for various values of the mass parameter. The value $m = 1$ practically coincides with the asymptotic value $m = \infty$.*

similar findings. The result is shown in figure 2, indicating that the approximation agrees remarkably well with the exact results. We also checked the approximations directly in figure 4. Comparison of the expressions for G e H using the approximations and the exact result shows that there is little discrepancy.

The approach to asymptotics in the computation of the potential has also been analysed. We have verified that it is very quick. Indeed, for reasonably low values of the mass the potential already shows the asymptotic value. We illustrated the behaviour in the case $m = 10$ in figure 3, which was done with the exact expressions.

3 Discussion

Here we worked out an approach for obtaining the semiclassical interquark potential for arbitrary values of the fermion mass parameter, generalizing our previous work[7], where only the infinite mass approximation was analysed. In that case, the expression for the effective action is local, and the interquark potential could be computed in closed form, showing

Figure 2: (Left) Potential function for infinite mass, and for $m = 1000$ using (17) and (18). (Right) Potential function for $m = 0.1$ using the exact results (14) and (15) and approximate forms (17) and (18).

explicitly that the model lives in a screening phase. We attempted here to go beyond the large mass limit. However, the expressions thus obtained are nonlocal, and we had to resort to numerical simulations. The results are nevertheless rewarding, especially in view of the extremely mild dependency upon the fermion mass, *i.e.* almost every physical quantity related to the screening potential is almost independent of the mass, for $0 \leq m \leq 1$

Figure 4: *Function G (left) and H (right) with $m = 1$, using the exact definitions (14) and (15), and the approximations (17) and (18).*

(we suppose $e = 1$) and achieves the asymptotic value already for m of order unit.

The screening obtained for all values of the mass parameter supports the observations obtained in two-dimensional QCD[4], where the screening phase also prevails almost universally (see also [2]). This opens up the discussion for a large number of interesting possibilities. In particular, it is interesting to stress that the same mechanism may work for the non-abelian case in three dimensions, since in the large mass limit the effective action turns out to be the non abelian generalization of the Maxwell Chern Simons theory. In an axial gauge, and in the weak coupling limit, the Maxwell Chern Simons action coincides with the abelian counterpart, and the same conclusions are expected. If one dares speculate that the mass dependence is as mild as we have obtained in the above discussion, then all conclusions can be carried over to the non abelian case as well, a tantalising result! This would imply an almost universal screening behaviour for low dimensional systems. We hope to come back to these interesting questions in a future work.

We also tested the approximative formulae (17) and (18), usually taken as a good approximation within 10% accuracy. The difference between the potential calculated using this approximations and the exact results is less than 10^{-2} , too small to be seen in figure 2.

We finally comment on the infinite and zero mass limits of the model. In the latter case we have to go beyond the quadratic approximation, since higher corrections have to be computed in a gauge theory where further powers of the external momenta show up in the computation of diagrams. One loop fermionic diagrams in gauge theories result in powers

of momentum and functions of momentum over mass, in general $f(\frac{p^2}{m^2})$. While the limit $p \rightarrow 0$ and $m \rightarrow \infty$ is unambiguous, the double limit $p \rightarrow 0$ and $m \rightarrow 0$ is not well defined, and depends on the order they are taken. Therefore strong infrared dependence on the mass may invalidate the procedure. Notice that the discussion of screening presupposes a large distance (namely small momentum) limit, which may not commute with the zero mass limit. The infinite mass limit obtained in the quadratic approximation is however expected to survive even in the non-quadratic regime. We hope to come back to these points in a future publication.
